RESEARCH MEMORANDUM

ALTITUDE INVESTIGATION OF 16 FLAME-HOLDER AND FUEL-SYSTEM

CONFIGURATIONS IN TAIL-PIPE BURNER

By Ralph E. Grey, H. G. Krull, and A. F. Sargent

SUMMARY

An investigation was conducted in an altitude chamber at the NACA Lewis laboratory to determine the performance of 16 flame-holder and fuel-system configurations in a short converging conical tail-pipe burner having a two-position exhaust nozzle. During the investigation, the engine was operated at rated engine speed, at a constant flight Mach number of 0.6, and over a range of tail-pipe-burner fuel-air ratios and altitudes.

Of the various configurations investigated, the best combustion performance and operable limits were obtained with a V-gutter flame holder and a radial fuel-injection system that provided a uniform fuel distribution over the flame holder and an increased mixing length between the fuel injectors and the flame holder. The maximum altitude limit obtained with one of the V-gutter flame holders was about 58,000 feet. The combustion efficiency, exhaust-gas temperature, and specific fuel consumption were only slightly affected by increases in altitude to 40,000 feet. The maximum altitude limits of the H-gutter and the H-gutter with a trailing V-gutter flame holders were 40,000 and 44,000 feet, respectively. The combustion efficiency and exhaust-gas temperature decreased and the specific fuel consumption increased rapidly with an increase in altitude for these configurations. With the jet nozzle open, starting by spark plug ignition was limited to altitudes of 30,000 feet and lower, whereas starts by the hot-streak ignition technique were obtained at all altitudes up to 45,000 feet, which was the maximum altitude at which starts were attempted.

INTRODUCTION

The altitude performance and operating characteristics of several types of flame-holder and fuel-injection system installed in the tail-pipe burner of a J35-A-21 turbojet engine were investigated in a 10-foot altitude test chamber at the NACA Lewis laboratory. The purpose of this

2176

investigation was to obtain a flame-holder and fuel-system configuration that would provide efficient combustion in a relatively short tail-pipe burner up to altitudes of at least 40,000 feet. Sixteen flame-holder and fuel-system configurations were investigated; ten configurations were supplied by the engine manufacturer and six were designed by NACA (based on information in reference 1). The tail-pipe burner, which was supplied as part of the engine, had a short converging conical burner section and a two-position exhaust nozzle. The outer shell of the tail-pipe burner remained unaltered during the investigation. Each configuration was operated over a range of altitudes at a flight Mach number of 0.6.

The data obtained for each configuration are presented in a manner to show the effects of fuel distribution and flame-holder design on net thrust, specific fuel consumption, exhaust-gas temperature, combustion efficiency, operable range of tail-pipe-burner fuel-air ratios, and maximum altitude limit. The combustion stability during tail-pipe-burner operation is also described and typical flame-holder failures that occurred during the investigation are discussed.

APPARATUS AND INSTRUMENTATION

Installation

The engine was installed in an altitude chamber as shown in figures 1 and 2. The engine was mounted on a thrust platform, which was connected through linkage to a calibrated balanced air-pressure diaphragm for measuring the thrust. The altitude chamber is 10 feet in diameter and 60 feet long. A honeycomb is installed in the chamber upstream of the test section to straighten and smooth the flow of inlet air. The forward baffle, which incorporated a labyrinth seal around the forward end of the engine, was used to separate the engine-inlet air from the exhaust and to provide a means of maintaining a pressure difference across the engine. A 14-inch butterfly valve was installed in the forward baffle to provide cooling air for the engine compartment. The rear baffle was installed to act as a radiation shield and to prevent recirculation of exhaust gases about the engine. The exhaust gas from the jet nozzle was discharged into an exhaust diffuser to recover some of the kinetic energy of the jet. Combustion in the burner was observed through a periscope located directly behind the engine.

Engine and Tail-Pipe Burner

A J35-A-21 engine, which includes a tail-pipe burner, was used in this investigation. The engine has a static sea-level thrust rating of

5100 pounds without tail-pipe burning at rated engine speed, 7900 rpm, and at a turbine-outlet temperature of 1300° F. At this operating condition, the air flow is approximately 86 pounds per second and the fuel consumption is 5740 pounds per hour. The over-all length of the engine is approximately 195 inches and the maximum diameter is 43 inches. The main components of the engine are an 11-stage axial-flow compressor, eight cylindrical through-flow combustors, a single-stage turbine, and a tail-pipe burner. Throughout the investigation, MIL-F-5624 fuel with a lower heating value of 18,900 Btu per pound and a hydrogen-carbon ratio of 0.179 was used in the engine and tail-pipe burner.

Drawings of the tail-pipe-burner assembly are schematically shown in figure 3. The tail-pipe-burner assembly was $87\frac{1}{2}$ inches long and consisted of three sections: (1) an annular diffuser followed by a short cylindrical section, (2) a converging conical burner, and (3) a two-position clamshell-type exhaust nozzle. The eyelids on this nozzle were secured in the open position throughout the investigation. The area of the exhaust nozzle in the open position was approximately 349 square inches. Fuel was supplied to the tail-pipe burner by an air-turbine fuel pump which was driven by air bled from the compressor.

Two flame-holder positions and two diffuser inner cones were used during the investigation. Flame-holder position 1 and the standard diffuser inner cone are shown in figure 3(a). Flame-holder position 2 and the modified diffuser inner cone are shown in figure 3(b). Position 1, which was the standard location for the engine manufacturer's flame holders, was located in the 6-inch cylindrical section about $2\frac{1}{2}$ inches downstream of the diffuser-outlet flange. Position 2 was located in the diffuser section about 4 inches upstream of the diffuser-outlet flange. The modified diffuser inner cone consisted of a standard diffuser inner cone cut off at the downstream end where the diameter was 6 inches and a cup section having a depth of $3\frac{1}{8}$ inches was installed at this point to provide a sheltered region for burning. The details of the flame holders and fuel systems will be discussed later.

Shell cooling of the burner section was accomplished by an ejector cooling shroud, which used the exhaust jet to induce a flow of cooling air over the burner shell. In the present investigation, the air for the burner cooling shroud was obtained from the test section of the altitude chamber at a pressure approximately equal to the altitude ambient pressure and at a temperature of about 100° F.

Two types of tail-pipe-burner ignition system were used. For the 10 manufacturer's configurations, ignition was provided by two spark

plugs projecting into the sheltered region of the outer annular gutter. For the NACA configurations, ignition was provided by a momentary increase in fuel flow to one of the engine combustors (reference 1). This excess fuel in one combustor caused a burst of flame through the turbine, thereby igniting the tail-pipe-burner fuel.

Flame Holders and Fuel Systems

Ten commercial flame-holder and fuel-system units (figs. 4 and 5), four NACA flame holders (fig. 6), and four NACA fuel-injection systems (fig. 7), in various combinations were investigated in the 16 configurations presented in this report. These configurations are classified into five basic types:

- (1) H-gutter flame holder with radial and annular fuel-injection manifold, configurations A through D
- (2) H-gutter flame holder with trailing V-gutter and radial and annular fuel-injection manifold, configurations E through I
- (3) Annular V-gutter flame holder with radial and annular fuelinjection manifold, configuration J
- (4) Annular V-gutter flame holder with radial fuel injectors, configurations K through 0
- (5) Radial V-gutter flame holder with radial fuel injectors, configuration P

The flame-holder and fuel-system units of configurations A through J were supplied by the engine manufacturer. The H-gutter of configurations A through I consisted of two parallel sides connected by a crossmember with holes to meter fuel and air into the sheltered region downstream of the flame holder. The annular trailing V-gutters (typical installation shown in fig. 4(d)) had an included angle of 36° , were $1\frac{1}{2}$ inches wide, and had a diameter generally intermediate between the diameters of the two annular H-gutters. The flame holder of configuration J was constructed of V-gutters. The fuel for these configurations was injected through radial and annular tubes immediately upstream of the flame holder.

The fuel system of configuration K and the fuel-system and flame-holder configurations L through P were NACA designs. All flame holders for these configurations were constructed of V-gutters. The fuel for these configurations was introduced normal to the direction of gas flow through radial fuel injectors.

A detailed description of each configuration is presented in table I. A comparison of the five basic configuration types is shown in the following table:

Conf rat	igu- ion		ŀ	lame hold	er	Fuel system				
Гуре	Fig- ure	Gutte cros sect Type	ss ion	Projected blocked area (percent)	Remarks	Fuel mixing length (in.) (a)	Injector figure	Remarks		
1	4(a) and 4(b)	H	5(a) to 5(c)	25.5 to 30.9	2 to 3 annu- lar gutters	1/8 to 1 <u>5</u>		Annular tubes connected by radial tubes		
2	4(c) to 4(f)	Η-∇	5(b) 5(d) and 5(e)	36.2 to 43.3	2 annular H- gutters with 1 or 2 trail- ing V-gutters 4 to 6 inches downstream	8		Same		
3	4(g)	٧	5(f)	28.9	2 annular gutters	$6\frac{1}{2}$		Same except tubes were streamlined		
4		٧	6(a) to 6(c)	28.9 to 35.2	2 annular gutters	3 to 10	7(a) to 7(c)	Radial tubes		
5		V	6(d)	26.6	Short radial gutters con- nected by one annular gutter	5 <u>5</u> 8	7(d)	Radial tubes		

^aMixing length is defined as distance from point of fuel injection to leading edge of flame holder.

Each part of the flame holder and fuel system is numbered on the photographs of figure 4 (configurations A through J) and details of the corresponding part are given in table II.

Instrumentation

Pressures and temperatures were measured at several stations in the engine and tail-pipe burner (fig. 2). Engine air flow was measured by use of survey rakes mounted at the engine inlet. Pressure and temperature instrumentation was installed to compute engine midframe air bleed and the air bleed from the compressor outlet that was used to drive the air turbine of the tail-pipe-burner fuel pump. A complete pressure and temperature survey was obtained at the turbine outlet (station 5, fig. 8(a)), and several of the 30 thermocouples at station 5 were used to obtain an indicated turbine-outlet temperature during operation. Static pressure measurements were taken at the burner inlet (station 6, fig. 8(b)) and total pressures were measured with a water-cooled survey rake at the exhaust-nozzle inlet (station 7, fig. 8(c)) 5 inches upstream of the exhaust-nozzle outlet. Engine and tail-pipe-burner fuel flows were measured by calibrated rotameters.

PROCEDURE

Tail-pipe-burner performance data were obtained over a range of tail-pipe-burner fuel-air ratios at a simulated flight Mach number of 0.6 and the following simulated altitudes:

Altitude (ft)					(COI	ıf:	igi	ırı	at:	io	1				
10,000	A	B	C	D				H		J		L			0	P
30,000	A:	В	C	D	E	F	G	H	I	J	K	L	M	N	0	P
35,000				D	E											
40,000	:	В			E			H		J	K	L	М	N	0	P

The engine-inlet-air total temperature and total pressure were regulated to correspond to NACA standard total temperature and pressure assuming 100-percent ram pressure recovery at each flight condition.

The symbols used in this report and the methods used in calculating the results are given in the appendix. Due to a questionable radiation effect on the thermocouples at the turbine outlet, the turbine-outlet temperature was calculated as shown in the appendix. This calculated temperature was used in plotting all curves presenting turbine-outlet data. Two fuel-air ratios are defined and used in computing and plotting the results of the investigation:

. 7

- (1) The tail-pipe-burner fuel-air ratio (f/a)_t is defined as the ratio of the tail-pipe-burner fuel flow to the engine air flow (air flow entering the compressor minus air bled from the compressor). This fuel-air ratio was used when only flight condition, rpm, and tail-pipe-burner fuel flow were recorded. The values of engine air flow were taken from an engine air-flow calibration curve.
- (2) The unburned-air tail-pipe-burner fuel-air ratio (f/a)_{ua} is defined as the ratio of the tail-pipe-burner fuel flow to the unburned-air flow entering the tail pipe (engine air flow minus the air burned in the engine). This fuel-air ratio was used when complete performance data were obtained.

The tail-pipe burner was started at a simulated flight Mach number of 0.6 and rated engine speed of 7900 rpm with the exhaust nozzle in the open position. For altitudes up to 30,000 feet, the tail-pipe burner was ignited and performance was obtained over a range of tail-pipe-burner fuel-air ratios. At altitudes above 30,000 feet, the tail-pipe burner was ignited at 30,000 feet, the simulated altitude was increased to the desired value, and data were obtained over a range of tail-pipe-burner fuel-air ratios.

At each flight condition with the engine operating at rated speed, the tail-pipe-burner fuel flow was varied from a minimum to a maximum. The minimum fuel flow was determined by: (1) imminent blow-out, or (2) a control limit (minimum flow rate of standard engine fuel regulator). The maximum fuel flow was determined by: (1) the indicated limiting turbine-outlet temperature of 1300° F (1760° R) measured by the operating thermocouples at station 5, (2) control limit (maximum flow rate of fuel regulator), (3) rough burning, or (4) blow-out. To determine the maximum operable altitude the burner was operated at constant fuel flow and flight Mach number while altitude was increased until blow-out occurred. Because actual blow-out of the burner was usually quite sudden, operating technique may account for scatter in the data of about ± 2000 feet.

RESULTS AND DISCUSSION

Operational Limits

The operational limits of all configurations are plotted in figure 9 against the tail-pipe-burner fuel-air ratio $(f/a)_t$. The four kinds of operational limits encountered, which were discussed in the procedure, are defined by the symbols of figure 9. For configurations A, B, C, and O, the maximum operable altitude was not determined but it is believed that this limit was generally about the same as the altitude

limit obtained for other configurations of the same basic type. The performance data and operational limits were not obtained at an altitude of 10,000 feet for some configurations because the flame holder was extremely hot and the service life under these conditions was very short.

The maximum altitude limit for basic configuration types 1 and 2 was generally about 40,000 feet with configurations E and H (basic type 2) reaching 44,000 feet. The altitude limit of basic configuration type 3 was about 45,000 feet, whereas that of basic types 4 and 5 was generally above 50,000 feet with configuration M (basic type 4) reaching 58,000 feet.

The rich operational limits of basic configuration types 1 and 2 generally resulted from blow-out, rough burning, or fuel-regulator limitations, whereas configuration types 3, 4, and 5 were restricted by limiting turbine-outlet temperatures. The occurrence of this limiting turbine-outlet temperature condition at relatively low fuel-air ratios indicates that basic configurations types 3, 4, and 5 were operating at higher combustion efficiencies than configuration types 1 and 2.

With the exception of configuration A, rough burning was encountered with all H-gutter configurations at rich fuel-air ratios. Rough burning would start suddenly with an attendant increase in noise level and vibration. When the fuel-air ratio was increased after rough burning was encountered, the noise level and vibration increased. An examination of the tail-pipe burner after such operation revealed broken and loosened bolts. In general, blow-out of basic configuration types 1, 2, and 3 was characterized by the flame shifting to the lower half of the flame holder and gradually diminishing until blow-out, whereas in configuration types 4 and 5, blow-out occurred suddenly.

A comparison of the operational limits of configurations B, H, J, L, and P, which represent the best operational limits and performance characteristics of each of the five basic configuration types, is shown in figure 10. Although configuration C appeared to be better than configuration B, it was not used for this comparison because the engine-inlet total temperature was 23° to 37° F below the NACA standard total temperature for all data obtained at an altitude of 30,000 feet.

Of all the configurations investigated, basic configuration types 4 and 5 had the highest altitude limits. An evaluation of these data indicates that the altitude limit was increased by the combined effects of (1) radial fuel injection with uniform distribution over the flame holder, (2) increased fuel mixing length, and (3) a V-gutter instead of H-gutter flame holder.

Performance Characteristics

The performance data obtained for each of the 16 configurations with a fixed-area conical exhaust nozzle is presented in table III. Performance data for five configurations, B, H, J, L, and P, are summarized in figures 11 through 16. These configurations were previously indicated to have the best operational limits and performance characteristics of each of the five basic configuration types. Performance data were plotted against the unburned-air tail-pipe-burner fuel-air ratio $(f/a)_{us}$. With the exhaust nozzle fixed in the open position, the burnerinlet conditions varied with fuel-air ratio as shown in figure 11. general, the turbine-outlet total temperature and pressure increased with tail-pipe-burner fuel-air ratio, whereas the burner-inlet velocity remained approximately constant. The turbine-outlet temperature survey used during operation for part of the investigation was found to be insufficient when later compared to the average of 30 thermocouples at station 5 and to the calculated value of turbine-outlet temperature. Consequently, some configurations were operated above limiting temperature. In such cases, the limiting turbine-outlet temperature operating point is indicated on the curves.

A comparison of combustion efficiencies and exhaust-gas temperatures for the five representative configurations over a range of fuel-air ratios at various altitudes is shown in figure 12. At an altitude of 30,000 feet and limiting turbine-outlet temperature (1760° R), configuration type 4 reached a combustion efficiency of 72 percent at a fuelair ratio of 0.035 and a peak combustion efficiency of 85 percent was obtained at a fuel-air ratio of 0.021. In comparison, at this same altitude and at a peak turbine-outlet temperature of 1660° R, the combustion efficiency obtained with the configuration type 1 was 32 percent at a fuel-air ratio of 0.07 and a maximum combustion efficiency of 54 percent was obtained at a fuel-air ratio of 0.023. The peak combustion efficiency of all configurations occurs at higher fuel-air ratios as altitude is increased. The peak combustion efficiency is shown to decrease rapidly with increasing altitude for configuration types 1, 2, and 3 but to decrease only slightly for configuration types 4 and 5. The effect of altitude on exhaust-gas temperature was to decrease the temperature at a constant fuel-air ratio or to increase the fuel-air ratio required to maintain a constant temperature as altitude was increased. These trends were considerably greater for configuration types 1, 2, and 3 than for 4 and 5. The rate of increase in exhaustgas temperature with fuel-air ratio became less after peak combustion efficiency had been reached. At all altitudes, the values of combustion efficiency and exhaust-gas temperature at a given fuel-air ratio were higher for configuration types 4 and 5 than for types 1, 2, and 3.

In some cases there were significant changes in combustion efficiency among the configurations within a given basic type. At an

altitude of 30,000 feet, where data were obtained for all configurations, the maximum combustion efficiency of the type 1 configurations varied from 51 to 66 percent and generally occurred at a fuel-air ratio of about 0.025. Maximum efficiency variation among type 2 configurations was somewhat greater, ranging from 57 to 66 percent and occurring at a fuel-air ratio of about 0.023. Among the type 4 configurations, peak efficiency varied from 77 to 85 percent and generally occurred at a fuel-air ratio of about 0.025.

The net thrust (fig. 13) reflects trends of exhaust-gas temperature and the specific fuel consumption reflects trends of exhaust-gas temperature and combustion efficiency. At an altitude of 30,000 feet and limiting turbine-outlet temperature (1760°R), type 4 configuration had a specific fuel consumption of 2.2 at a fuel-air ratio of 0.035, whereas at the peak turbine-outlet temperature of 1660°R, type 1 configuration had a specific fuel consumption of 3.7 at a fuel-air ratio of 0.07. In general, at a given tail-pipe-burner fuel-air ratio, the net thrust was higher and the specific fuel consumption was lower for configuration types 4 and 5 at all altitudes and the margin between these types and configuration types 1, 2, and 3 became increasingly greater as altitude was increased.

The relative performance of the five configuration types is illustrated in terms of net thrust and specific fuel consumption in figure 14 for an altitude of 30,000 feet. The data indicated that for a given net thrust, configuration types 4 and 5 operated with lower specific fuel consumption than configuration types 1, 2, and 3. Therefore on the basis of high altitude operational limits and best performance, configuration type 4 and type 5 were the best investigated for this particular burner geometry. The burner performance was improved by the same combined factors that improved the altitude limits, namely: (1) radial fuel injection with uniform distribution over the flame holder, (2) increased fuel mixing length, and (3) a V-gutter flame holder.

Operational Characteristics

The tail-pipe-burner losses presented as $(P_5-P_7)/P_5$ in figure 15 indicate a trend of decreasing pressure-loss ratio with a decrease in blocked area for all configurations. The pressure-loss ratio for the two best configuration types, 4 and 5, was in each case lower than or equal to that of the other configuration types. The pressure-loss ratio remained approximately constant with increasing fuel-air ratio and altitude. Although the pressure-loss ratio remained constant, the actual drop in pressure across the tail-pipe burner increased with increasing fuel-air ratio and turbine-outlet total pressure. The combination of ejector and nozzle losses caused a decrease in thrust of about 1.5 percent as shown in figure 16.

For this particular tail-pipe-burner installation, the over-all dimensions were fixed; consequently, to conserve tail-pipe length, the burner-inlet diffuser was relatively short. In figure 17, the velocity profiles at the diffuser inlet (station 5) and outlet (station 6) show a high velocity gradient near the outer walls and a separation from the inner cone at the inlet with a substantial growth of the boundary layer along the inner cone. It was found during the investigation that this separation along the inner cone and the exhaust-gas swirl and attendant flow separation from the lee side of the long support struts for the inner cone provided regions where burning occurred when fuel was injected near the leading edge of the struts. When fuel was injected near the inner cone and between the trailing edge of the struts and the diffuser outlet, burning took place in the region of separation from the inner cone. Therefore, the separation from both the inner cone and support struts dictated the maximum distance upstream of the diffuser outlet that the fuel injectors could be placed to increase the fuel mixing length. To increase the mixing length beyond these limits would require shortening the diffuser support struts in addition to redesigning the diffuser to prevent flow separation.

In obtaining performance data for the investigation, operation of the nozzle eyelids was not required, consequently they were secured in the open position. With the exhaust nozzle in the open position, the lowered temperatures and pressures in the tail pipe imposed more severe starting conditions on the burner than are normally encountered with the nozzle closed. The two spark plugs which were provided with each of the commercially manufactured configurations usually permitted starts up to an altitude of 30,000 feet. The hot-streak ignition technique, which was used in each of the NACA configurations, permitted starts at all altitudes up to 45,000 feet, which was the maximum altitude at which starts were attempted.

After about 70 hours of operation, the tail-pipe-burner shell was in good condition except for a few minor wrinkles. Considerable difficulty was experienced with the operation of the two-position variable-area exhaust nozzle because of warping and binding of the eyelids, which was probably due to misalinement or maladjustment of the actuator and actuating linkages.

A number of flame holders failed structurally during the investigation because of burning upstream of the flame holder and because of poor fuel distribution. Examples of failures are shown in figures 18 to 21. Typical failures of the H-gutter and the trailing V-gutter are shown in figures 18 and 19. Usually, failures which occurred at an intersection of the V-gutters did not appear to be a fault of the weld, inasmuch as the welds were usually in good condition as shown in figure 20. In figure 21, the intense burning in the sheltered region of

the V-gutter is evident by the burning out of the reinforcing tubing near the leading edge of the gutter. The V-gutter failures could usually be prevented by: (1) increasing the diameter of the flame-holder inner annular V-gutter (if it were in the region of burning off the inner cone), and (2) constructing the flame holders of heavier gage materials.

During the investigation of the configurations which used the radial fuel injectors, considerable trouble was experienced with coking of the fuel-injector tubes. Radiation from the flame holder may have aggravated coking; locating the fuel injectors upstream might alleviate coking. No definite information was obtained as to the cause of this coking, but in the use of internal fuel manifolds (basic configuration types 1, 2, and 3) there were no coking problems. These manifolds had no dead ends in the flow passages which may have been the starting place for coking.

SUMMARY OF RESULTS

In an investigation of a J35-A-21 turbojet engine with a short converging conical tail-pipe burner having a two-position exhaust nozzle, a number of flame-holder and fuel-system configurations were evaluated at rated engine speed and at a constant flight Mach number of 0.6 for a range of altitudes and tail-pipe-burner fuel-air ratios. The following results were obtained:

- 1. The performance characteristics and altitude operating limits of the tail-pipe burner were improved by the combined effects of (1) radial fuel injection with uniform distribution over the flame holder, (2) increased fuel mixing length, and (3) a V-gutter-type flame holder.
- 2. A maximum altitude limit of about 58,000 feet was obtained with a V-gutter flame holder. In most cases the altitude limit with the V-gutter flame holders was about 50,000 feet, and combustion efficiency, exhaust-gas temperature, and specific fuel consumption were only slightly affected by changes in altitude up to 40,000 feet.
- 3. The maximum altitude limits of the H-gutter and the H-gutter with a trailing V-gutter flame holder were 40,000 and 44,000 feet, respectively. With these configurations, the combustion efficiency and exhaust-gas temperature decreased and the specific fuel consumption increased rapidly with an increase in altitude.
- 4. The short tail-pipe-burner inlet diffuser had a high velocity gradient near the outer wall and separation existed at the inlet on the

176

7

inner cone with a substantial growth of the boundary layer along the inner cone.

5. With the two-position exhaust nozzle open, starting by spark plug ignition was limited to altitudes up to 30,000 feet, whereas starts with the hot-streak ignition technique were obtained at all altitudes up to 45,000 feet, which was the maximum altitude at which starts were attempted.

Methods of Calculation

Flight speed and Mach number. - The simulated flight speed and Mach number at which the engine and tail-pipe burner were operated were determined from the equations

$$V_{O} = \sqrt{2gR \frac{\gamma_{1}}{\gamma_{1}-1} T_{1} \left[1 - \left(\frac{p_{O}}{P_{1}}\right)^{\frac{\gamma_{1}-1}{\gamma_{1}}}\right]}$$
 (1)

2]

$$M_{0} = \sqrt{\frac{2}{\gamma_{1}^{-1}} \left[\left(\frac{P_{1}}{p_{0}} \right)^{\frac{\gamma_{1}-1}{\gamma_{1}}} - 1 \right]}$$
 (2)

where γ was assumed to be 1.4.

Gas flow. - The compressor-inlet air flow was computed as

$$W_{a,1} = \frac{A_{1}p_{1}}{\sqrt{RT_{1}}} \sqrt{2g \frac{\gamma_{1}}{\gamma_{1}-1} \left[\left(\frac{P_{1}}{p_{1}}\right)^{\frac{\gamma_{1}-1}{\gamma_{1}}} - 1\right] \left(\frac{P_{1}}{p_{1}}\right)^{\frac{\gamma_{1}-1}{\gamma_{1}}}}$$
(3)

where γ was assumed to be 1.4 and the total temperature was assumed to be equal to the indicated temperature inasmuch as the thermocouple recovery factor was 0.96. The engine air flow at station 3 was calculated by subtracting the midframe leakage and the air flow required to drive the tail-pipe-burner fuel pump from the compressor-inlet air flow. The midframe air leakage and tail-pipe-burner fuel-pump air flow were calculated in a similar manner to the compressor-inlet air flow. The total gas flow at the turbine outlet was calculated as

$$W_{g,5} = W_{a,3} + \frac{W_{f,\Theta}}{3600}$$
 (4)

The total gas flow at the exhaust-nozzle throat was computed as

$$W_{g,8} = W_{g,5} + \frac{W_{f,t}}{3600}$$
 (5)

<u>Turbine-outlet temperature.</u> - The turbine-outlet temperature T_5 was the measured average of 30 thermocouples. Due to questionable radiation effect on T_5 , a calculated turbine-outlet temperature T_5 , c was obtained by

$$H_{5} = \left(\frac{f}{a}\right)_{e} \left[\eta_{e} h_{c} + \lambda \middle|_{T_{r}}^{5}\right] + H_{a,1}$$
 (6)

The value of $T_{5,c}$ was then obtained from H_5 and enthalpy charts. A value of 0.96 was selected for the engine combustion efficiency η_e from an altitude calibration of a similar engine. The term λ accounts for the difference between the enthalpy of the carbon dioxide and water

TILAT.

vapor in the burned mixture and the enthalpy of the oxygen removed from the air by their formation (reference 2). Comparison of these turbine-outlet temperatures can be made in table III.

Tail-pipe-burner inlet velocity. - The tail-pipe-burner inlet velocity was calculated by use of the continuity equation. The static pressure and area were measured at station 6. The total pressure and temperature measurements from station 5 were used assuming no loss between the two stations.

$$v_{6} = \frac{v_{g} RT_{5,c}}{A_{6} p_{6}} \left(\frac{p_{6}}{P_{5}}\right)^{\frac{\gamma_{6}-1}{\gamma_{6}}}$$
(7)

The gas flow at station 6 was $W_{g,5}$ or $W_{g,8}$ dependent on the configuration inasmuch as in some configurations the tail-pipe-burner fuel was introduced upstream of station 6 and in others it was introduced downstream of station 6.

Tail-pipe-burner fuel-air ratio. - Two tail-pipe-burner fuel-air ratios are used in this report and are defined as follows:

(1) The ratio of the tail-pipe-burner fuel flow to engine-air flow,

$$\left(\frac{f}{a}\right)_{t} = \frac{W_{f,t}}{3600 W_{a,3}} \tag{8}$$

(2) The ratio of the tail-pipe-burner fuel flow to the unburned air entering the tail-pipe burner,

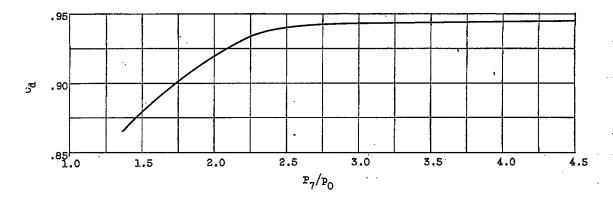

$$\left(\frac{f}{a}\right)_{ua} = \frac{W_{f,t}}{3600 W_{a,3} - \frac{W_{f,e}}{0.0667}}$$
 (9)

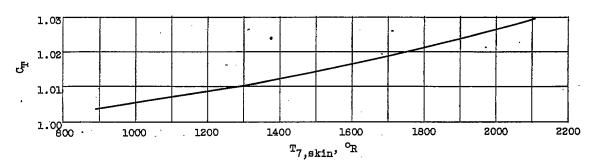

The assumption used in obtaining this equation was that the fuel injected in the engine was completely burned. The value of 0.0667 is the stoichiometric fuel-air ratio for the fuel used.

Exhaust-gas temperature. - The exhaust-gas temperature was determined by

$$T_{8} = \left(\frac{A_{8} C_{d} C_{T} p_{8}}{W_{g,8}}\right)^{2} \frac{2g}{R} \left(\frac{\gamma_{8}}{\gamma_{8}-1}\right) \left[\frac{p_{7}}{p_{8}}\right]^{\frac{\gamma_{8}-1}{\gamma_{8}}} - 1 \left(\frac{p_{7}}{p_{8}}\right)^{\frac{\gamma_{8}-1}{\gamma_{8}}}$$
(10)

The flow coefficient $C_{
m d}$ was obtained from reference 3. The exhaustnozzle throat area $A_{
m S}$ was measured at room temperature. Values of the thermal expansion ratio $C_{
m T}$ of the exhaust nozzle were determined from the thermal expansion coefficient for the exhaust-nozzle material and the measured skin temperature.

Exhaust-nozzle-throat static pressure p₈ was determined as follows:

When

$$\frac{P_7}{p_0} < \left(\frac{\gamma_8 + 1}{2}\right)^{\frac{\gamma_8}{\gamma_8 - 1}}$$

176

then

$$p_8 = p_0$$
 (subsonic flow)

When

$$\frac{P_7}{P_0} \ge \left(\frac{\gamma_8 + 1}{2}\right)^{\frac{\gamma_8}{\gamma_8 - 1}}$$

then

$$p_8 = \frac{P_7}{\frac{\gamma_8}{\gamma_8 - 1}} \text{ (sonic flow)}$$

$$\left(\frac{\gamma_8 + 1}{2}\right)^{\frac{\gamma_8}{\gamma_8 - 1}}$$

The nozzle-throat total pressure was assumed equal to the total pressure measured at station 7 (5 in. upstream of the throat). The values of γ_8 were obtained from charts of γ against f/a and T from the first approximation of T_8 which was calculated using the value of $\gamma=1.24$.

Tail-pipe-burner combustion efficiency. - The tail-pipe-burner combustion efficiency was calculated by the equation

$$\eta_{t} = \frac{H_{a} \int_{1}^{8} + \left(\frac{f}{a}\right)_{e} \lambda \int_{T_{r}}^{8} + \left(\frac{f}{a}\right)_{t} \lambda \int_{T_{r}}^{8} - \left(\frac{f}{a}\right)_{e} \eta_{e} h_{c}}{h_{c} \left[\left(\frac{f}{a}\right)_{t} + \left(\frac{f}{a}\right)_{e} (1 - \eta_{e})\right]}$$
(11)

Dissociation was not considered in the calculation of combustion efficiency inasmuch as its effect is negligible for temperatures of up to 3600° R. The engine fuel was not assumed to be burned completely in the engine. The unburned engine fuel was charged to the tail-pipe burner. The engine combustion efficiency was selected to be a value of 0.96 which was obtained from an altitude calibration of this engine type.

Thrust. - The actual jet thrust was calculated by the equation

$$F_{j} = F_{d} + A_{g} (P_{1} - P_{0})$$
 (12)

where F_d was obtained from balanced air-pressure diaphragm measurements. Net thrust was obtained from the actual jet thrust by

$$F_{n} = F_{j} - \frac{W_{a, 1} V_{0}}{g}$$
 (13)

The theoretical jet thrust was calculated as

$$F_{j,8} = W_{g,8} \sqrt{\frac{2R}{g} \frac{\gamma_8}{\gamma_8-1} T_8 \left[1 - \left(\frac{p_8}{P_7}\right)^{\frac{\gamma_8-1}{\gamma_8}}\right]} + A_8 C_T \left[p_8 - p_0\right] (14)$$

The values of p_8 , γ_8 , and C_T used are explained in the discussion of equation (10).
